Gas Detectors

3. Gas Detectors

3 Gas Detectors

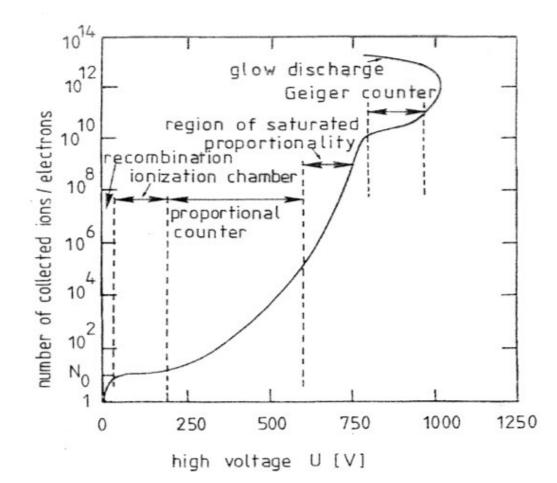

- General introduction
- Charge Transport
- Gas amplification
- Ionization chamber
- Proportional counter
- Drift chambers
- Cylindrical wire chambers
- Jet drift chambers
- Time Projection Chamber TPC

3.1 General introduction

Principle

- ionizing particle creates primary and secondary charges via energy loss by ionization (Bethe-Bloch, chapter 2) N₀ electrons and ions
- charges drift in electric field
- generally gas amplification in the vicinity of an anode wire
- signal generation

different operation modes depending on electric field strength

modes of operation of gas detectors (after F. Sauli 1977, lecture notes)

Charge carriers in layer of thickness L for a mean energy W to produce electron-ion pair

mean number:

$$\langle n_t \rangle = rac{L \langle rac{dE}{dx}
angle_{ ext{ion}}}{W}$$

about 2 – 6 times the primary number (see chapter 2) important for spatial resolution: secondary ionization by δ -electrons happens on length scale 10 μm

e.g. $T_e = 1$ keV in iso-butane $\rightarrow R = 20 \ \mu m$

ionization statistics:

 $\lambda = 1/\sigma_I \rho$ mean distance between ionization events with cross section σ_I mean number of ionization events $\langle n \rangle = L/\lambda$

Poisson distribution about mean $\langle n \rangle$

$$P(n, \langle n \rangle) = rac{\langle n \rangle^n \exp(-\langle n \rangle)}{n!}$$

and specifically probability for no ionization

$$P(0, \langle n \rangle) = \exp(-\langle n \rangle) = \exp(-L/\lambda)$$

efficiency of gas detectors allows determination of λ and hence σ_I typical values:

$$\begin{array}{c|c}
\lambda \text{ (cm)} \\
\hline
\text{He} & 0.25 \\
\text{air} & 0.053 \\
\text{Xe} & 0.023
\end{array}$$

$$ightarrow \sigma_{I} = 10^{-22} \ {
m cm}^2$$
 or 100 b

3.2 Charge Transport - Ion mobility

lons drift along field lines in external E-field plus superimposed random thermal motion ion transfers in collisions with gas atoms typically half of its energy \rightarrow kinetic energy of ion is approximately thermal energy

$$\langle au_{\mathsf{ion}}(ec{E})
angle \simeq \langle au_{\mathsf{ion}}(\mathsf{therm})
angle = rac{3}{2}kT$$

drift velocity in direction of \vec{E} : develops from one collision to the next (thermal velocity has random orientation relative to \vec{E})

assume instantaneous ion velocity due to electric field $u_e = 0$ at t = 0 and typical collision time au

 \rightarrow directly prior to collision $\vec{u}_e = \vec{a} \cdot \tau = \frac{e\vec{E}}{M} \cdot \tau$

 $\rightarrow \text{ drift velocity of ion } \vec{v}_{D^+} = \langle \vec{u}_e \rangle = \frac{1}{2} u_e = \frac{e\vec{E}}{2M} \tau = \mu_+ \vec{E} \qquad \mu_+ \equiv \text{ ion mobility}$ where $\tau \propto \lambda \propto 1/\sigma_+ \simeq \text{ constant since } \langle T_{\text{ion}} \rangle \text{ essentially thermal.}$

e.g. $C_4H_{10}^+$ in C_4H_{10} $\mu_+ = 0.61 \frac{\text{cm/s}_{v_{0^+}}}{\text{V/cm}}$ at $E = 1 \text{ kV/cm} \rightarrow v_{0^+} = 0.6 \text{ cm/ms}$ typical drift distances $\text{cm} \rightarrow \text{typical ion drift times ms}$

Electron mobility I

Electrons drift towards anode of a gas detector in a given field with a constant velocity, measurement of drift time allows to determine point of ionization.

$$\Delta t = \frac{L}{v_D}$$

equation of motion of electron in superimposed \vec{E} and \vec{B} -fields (Langevin):

$$mrac{{
m d}ec v}{{
m d}t}=eec E+e(ec v imesec B)+ec Q(t))$$

with instantaneous velocity \vec{v} and a stochastic, time dependent term Q(t) due to collisions with gas atoms

assume: collision time au \vec{E} and \vec{B} constant between collisions consider $\Delta t \gg \tau$ (averaging) $\rightarrow Q(t)$ is friction

steady state is reached when net force is zero, defines drift velocity v_D

$$\langle m \frac{d\vec{v}}{dt} \rangle = e(\vec{E} + \vec{v}_D \times \vec{B}) - \underbrace{\frac{m}{\tau} \vec{v}_D}_{\text{Stokes-type}} = 0$$

Electron mobility II

$$B = 0: \quad \vec{v}_D = \mu_- \vec{E} \quad \text{with} \quad \mu_- = \frac{e\tau}{m} \equiv \mu$$
$$B \neq 0: \quad \vec{v}_D = \mu_- \vec{E} + \omega \tau (\vec{v}_D \times \vec{B}) \quad \text{with Larmor frequency} \quad \omega = \frac{eB}{m} \quad (\text{see below})$$

Compared to ions, $\mu_+ \ll \mu_-$ since $M \gg m$

2 types of gases

a) hot gases: atoms with few low-lying levels, electron loses little energy in a collision with atom $\rightarrow T_e \gg kT$ acceleration in E-field and friction lead to constant v_D for a given \vec{E} 'free fall with friction' but $\lambda(T_e) \simeq \lambda(|\vec{E}|)$ and $\mu \propto \tau \propto 1/\sigma(|\vec{E}|)$ not constant.

typical drift velocity: $v_D = 3 - 5 \text{ cm}/\mu \text{s}$ for 90% Ar/10% CH₄ (typically saturating with E)

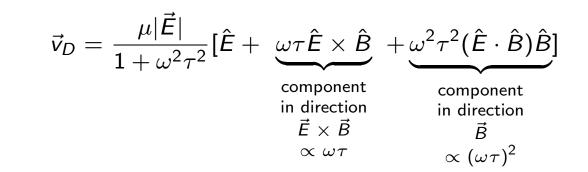

- b) cold gases: many low-lying degrees of freedom
 - \rightarrow electrons lose kinetic energy they gain in between collisions (similar to ions)

$$T_e \simeq kT$$
 $\mu \simeq ext{constant}$ $v_D \propto |E|$

examples: Ar/CO_2 or Ne/CO_2

$$\begin{array}{ll} \mbox{in latter:} \ \mu \simeq 7.0 \cdot 10^{-3} \ \mbox{cm}^2/\mu \mbox{s V at } 10\% \ \mbox{CO}_2 & \mbox{or } v_D = 2 \ \mbox{cm}/\mu \mbox{s at } 300 \ \mbox{V/cm} \\ 3.5 \cdot 10^{-3} \ \mbox{cm}^2/\mu \mbox{s V at } 20\% & v_D = 1 \ \mbox{cm}/\mu \mbox{s} \end{array}$$

Drift in combined \vec{E} and \vec{B} -fields

 \hat{E} , \hat{B} : unit vectors in direction of E- and B-field

Electron loss

with some probability a free electron is lost during drift

a) recombination $ion^+ + e^$ decrease in number of negative (and positive) charge carriers

$$-\frac{\mathrm{d}N^{-}}{\mathrm{d}t} = p_r \cdot \rho^{+} \rho^{-} \qquad p_r : \text{coefficient of recombination} \simeq 10^{-7} \text{ cm}^3/\text{s}$$

generally not important

b) electron attachment

on electro-negative molecules, probability can be large

$$e^- + M o M^-$$
 for $T_e \simeq 1 \; eV$

otherwise dissociative attachment

 $e^- + XY \rightarrow X + Y^-$

for gases like O₂, Cl₂, freon, SF₆ probability per collision is of order 10^{-4} capture coefficient p_c is strongly energy dependent (in many gases there is a minimum at 1 eV 'Ramsauer effect')

electron undergoes order of 10^{11} collisions/s \rightarrow for drift time of 10^{-6} s fraction lost X_{loss} depends on partial oxygen pressure

$$X_{
m loss} = 10^{-4} \cdot (10^{11}/
m s) \cdot (10^{-6} \
m s) \cdot P_{
m O_2}/P_{
m atm}$$

 \rightarrow less than 1% lost for $P_{\rm O_2}/P_{\rm atm} \leq 10^{-3}$

Remark: in presence of certain quencher gases such as CO_2 the effect of O_2 is enhanced by multistep catalytic reaction

- 10 ppm O₂ can lead to 10% loss within 10 μ s \rightarrow need to keep oxygen level low in gas.

Diffusion I

Original ionization trail diffuses (spreads apart) with drift time \rightarrow effect on space point and momentum resolution, ultimate limit

a) only thermal motion $(|\vec{E}| = |\vec{B}| = 0)$ mean thermal velocity

 $\begin{array}{rcl} \langle v \rangle &=& \frac{\lambda}{\tau} & & \lambda \text{ me} \\ \langle \tau_e \rangle &=& \frac{1}{2} m \langle v \rangle^2 \end{array}$

 λ mean free path au time between collisions

for a point-like source at time t = 0, collisions between electrons and gas atoms (molecules) \rightarrow smearing: spread of charge cloud at time of first collision

$$R^2 = 2\lambda^2$$

and after $n = t/\tau$ collisions

$$\sigma^2(t) = 2\lambda^2 t/ au$$

define diffusion coefficient

for
$$|\vec{E}| = |\vec{B}| = 0$$
 $D = D_0 = \frac{\lambda_0^2}{\tau} = \frac{2\langle T_e \rangle}{m} \tau$

 $D = -\frac{\sigma^2(t)}{2}$

Diffusion II

diffusion is isotropic

longitudinal diffusion coefficient
$$D_{0L} = \frac{1}{3} \frac{\lambda_0^2}{\tau}$$

transverse diffusion coefficient $D_{0T} = \frac{2}{3} \frac{\lambda_0^2}{\tau}$

 $\begin{array}{ll} \rightarrow \text{ after time } t \text{ charge cloud has width} & \sigma(t) = \sqrt{D2t} \\ \text{respectively, in each dimension} & \sigma_x(t) = \sigma_y(t) = \sigma_z(t) = \sqrt{\frac{1}{3}D2t} \\ \text{charge distribution Gaussian} & N(x) = c \cdot \exp(-\frac{x^2}{2\sigma_x^2}) \end{array}$

diffusion equation: charge density $\rho(\vec{r}, t)$ for conserved electron current \vec{j} defined by

$$\begin{aligned} \frac{\partial \rho}{\partial t} + \nabla \cdot \vec{j} &= 0 \\ \text{without field,} \quad \vec{j} &= -D\nabla \rho \implies \frac{\partial \rho}{\partial t} &= D\Delta \rho \\ \text{solved by} \qquad \qquad \rho(\vec{r}, t) &= c \cdot \exp(-\frac{\vec{r}^2}{4Dt}) \end{aligned}$$

Diffusion III

hot gases: $\langle T_e \rangle \gg \frac{3}{2}kT$ *D* large cold gases: $\langle T_e \rangle \simeq \frac{3}{2}kT$ *D* small

with 1-dim diffusion $D = \frac{2\langle T_e \rangle}{3m} \tau$

and $\mu = \frac{e}{m} \tau$ (B=0)

$$\langle T_e \rangle = \frac{3}{2} e \frac{D}{\mu}$$

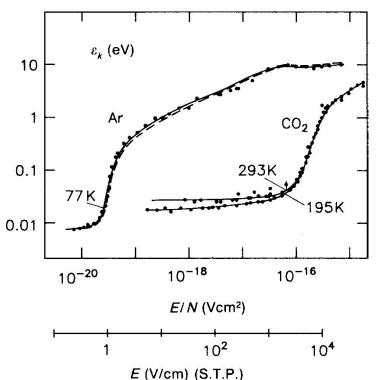

can define a characteristic energy

$$\epsilon_k = \frac{2}{3} \langle T_e \rangle = e \frac{D}{\mu}$$

diffusion of cloud after distance L

$$\sigma_x^2 = 2Dt = 2D\frac{L}{\mu E} = \frac{2\epsilon_k}{eE}L \qquad (1)$$

for hot gas the same characteristic energy is reached at much lower T

characteristic energy of electrons in Ar and CO_2 as a function of the reduced *E*. The electric field under normal conditions is also indicated. The parameters refer to temperatures at which the measurements were made.

Diffusion IV

b) diffusion in B-field

$$\vec{B} = B\vec{e}_z$$

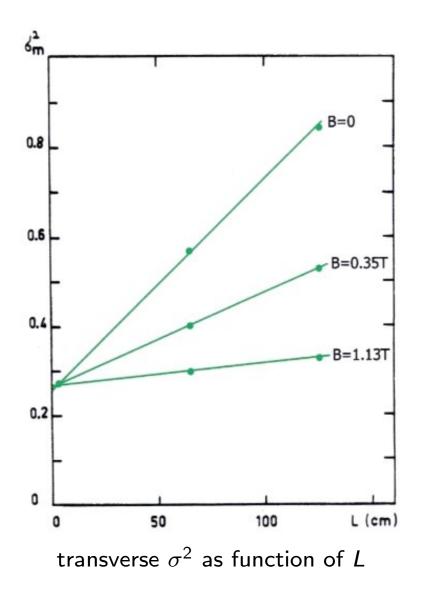

along *B* no Lorentz force $D_L(B) = D_{0L} = \frac{1}{3}D_0$

in transverse direction Lorentz force helps to keep charge cloud together, i.e. it counteracts diffusion

$$D_T(B) = \frac{D_{0T}}{1 + \omega^2 \tau^2}$$

for \vec{B} large $\rightarrow \omega \tau \gg 1$ $D_T(B) \ll D_{0T}$

e.g. Ar/CH₄ at
$$B = 1.5~T~~D_T(1.5~T) \simeq rac{1}{50} D_{0T}$$

Diffusion V

c) diffusion in electric field: ordered drift along field superimposed to statistical diffusion mobility μ is function of $\langle T_e \rangle$

$$ec{v}_D = \mu(\langle T_e
angle) \cdot ec{E}$$

 \rightarrow energy spread leads to longitudinal spreading of electron cloud $D_L \neq \frac{1}{2}D_T$

statistical transverse diffusion not affected by E-field

in hot gases: for large E, $D_L > D_T$ and values are large

in cold gases: $D_L \simeq D_T$ small

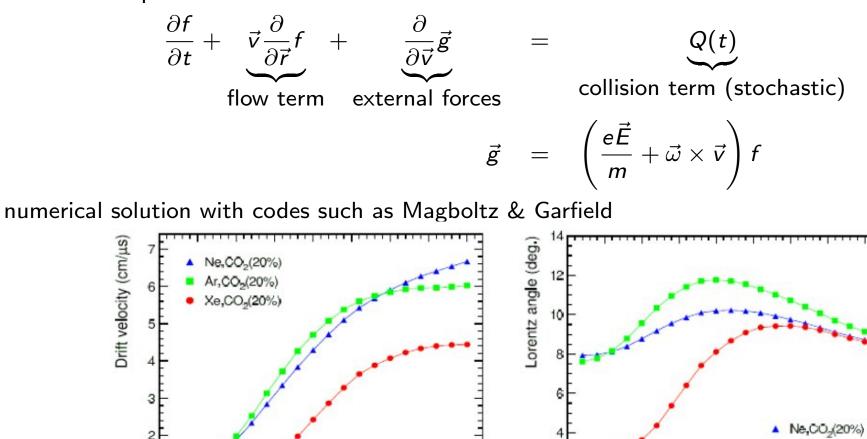

$$\sigma^{2}(t) = 2Dt = 2D\frac{L_{D}}{v_{D}} = \frac{2kT}{e|\vec{E}|}L_{D}$$
$$\frac{\sigma^{2}(t)}{L_{D}} = \frac{2kT}{e|\vec{E}|}$$

longitudinal diffusion width $\sigma_x/\sqrt{L_D}$ after 1 cm of drift

Exact solution

of drift and diffusion by solving a 'transport equation' for electron density distribution $f(t, \vec{r}, \vec{v})$ Boltzmann-equation:

Lorentz angle: angle between E-field and drift velocity of electrons in presence of B not \perp to E

1.5

1.25

1.75

Drift field E (kV/cm)

B=0.4 T

0.75

0.5

0.5

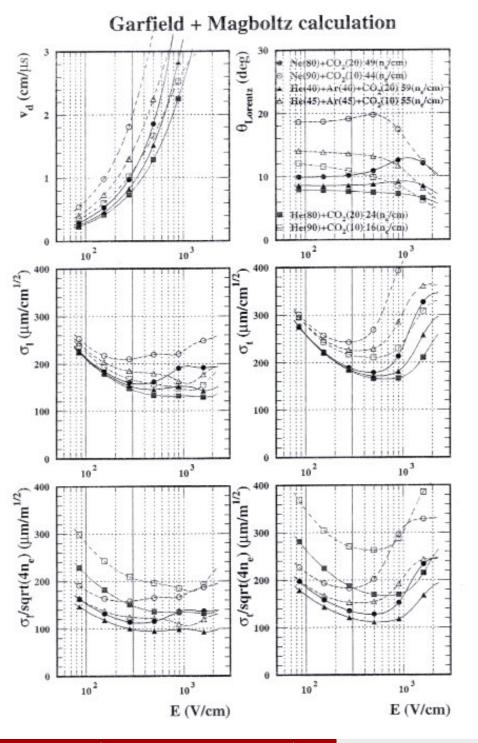

0.75

0.25

Ar,CO2(20%) Xe,CO2(20%)

1.5

Drift field E (kV/cm)

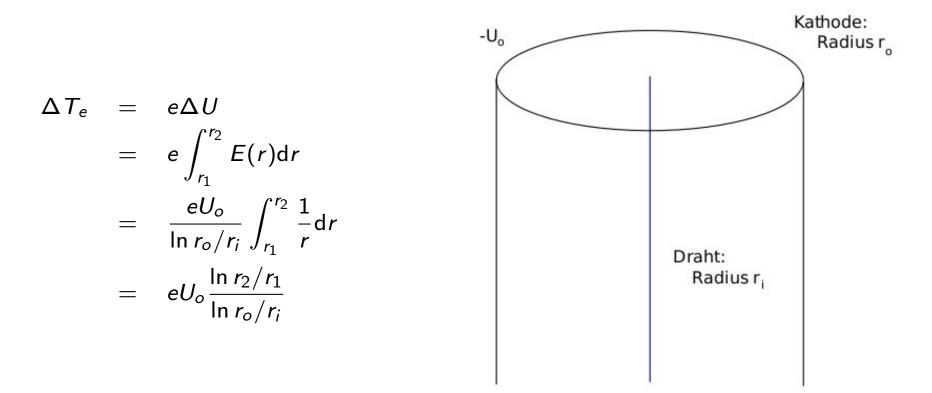

Drift velocity (top left), Lorentz angle (top right), longitudinal and transverse diffusion constants (middle) and longitudinal and transverse diffusion constants normalized to the square root of the number of charge carriers (bottom) for different mixtures of noble gas and CO_2 .

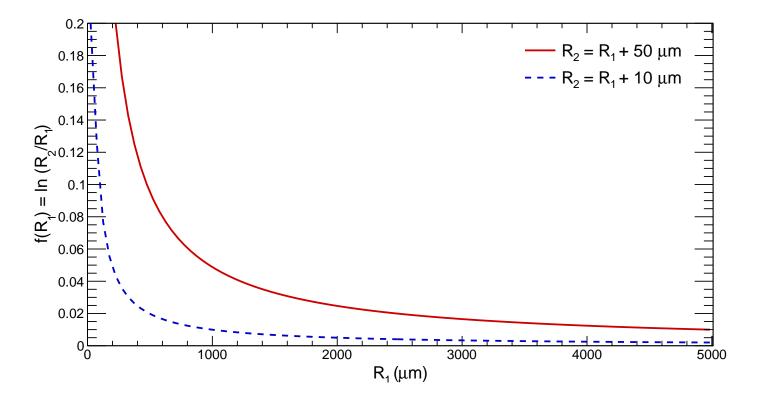

Lorentz angle: angle between E-field and drift velocity of electrons in presence of B not \perp to E

3.3 Gas amplification

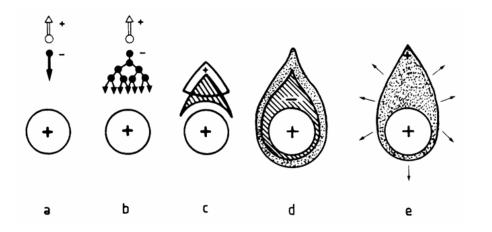

in case the anode is a (thin) wire, E-field in vicinity of wire very large $E \propto 1/r$ and the electron gains large kinetic energy.

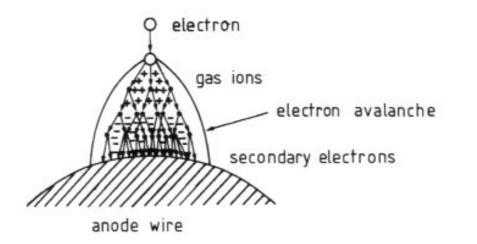

in order to obtain large E and hence large ΔT_e we use very thin wires $(r_i \simeq 10 - 50 \ \mu m)$ within few wire radii ΔT_e is large enough for secondary ionization strong increase of $E \rightarrow$ avalanche formation for $r \rightarrow r_i$.

Avalanche formation in vicinity of a thin wire

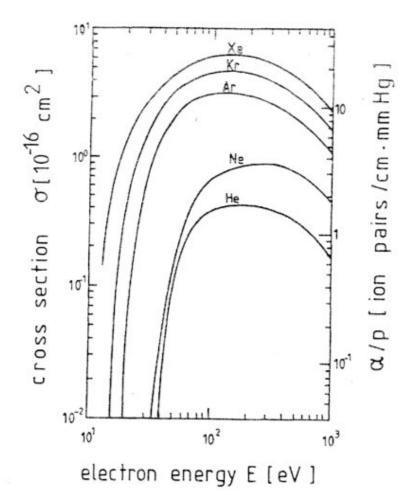

Temporal and spatial development of an electron avalanche

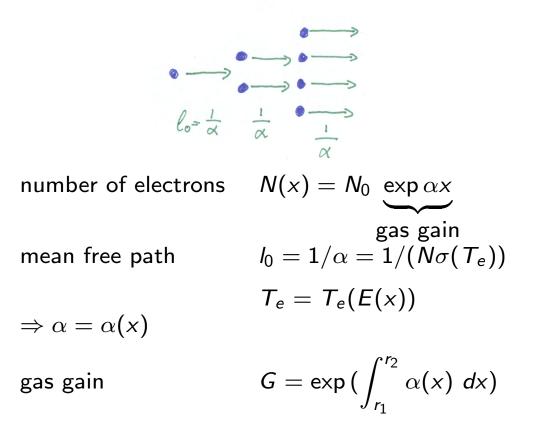

Photographic reproduction of an electron avalanche. The photo shows the form of the avalanche. It was made visible in a cloud chamber by droplets which have condensed on the positive ions.

Illustration of the avalanche formation on an anode wire in a proportional counter. By lateral diffusion a drop-shaped avalanche develops.

First Townsend coefficient α

Energy dependence of the cross section for ionization by collision.

Typically $10^4 - 10^5$, up to 10^6 possible in proportional mode. limit: discharge (spark) at $\alpha x \simeq 20$ or $G = 10^8$ 'Raether-limit'

Gas amplification

Second Townsend coefficient

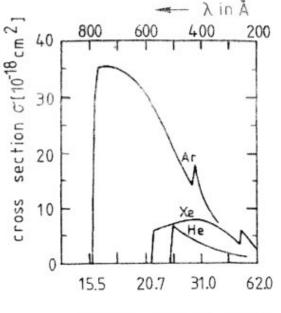

excitation of gas generates UV-photons which in turn can lead to photo effect in gas and on cathode wire contributing thus to avalanche.

$$\gamma = rac{\# \text{ photo effect events}}{\# \text{ avalanche electrons}}$$

gas gain including photo effect

$$G_{\gamma} = \underbrace{G}_{\text{no}} + \underbrace{G(G\gamma)}_{\text{one}} + \underbrace{G(G\gamma)^2}_{\text{two}} + \ldots = \frac{G}{1 - \gamma G}$$

photo effect events

photon energy E[eV]

Energy dependence of the cross section for photoionization

limit: $\gamma G \rightarrow 1$ continuous discharge independent of primary ionization

to prevent this, add to gas so-called quench-gas which absorbs UV photons strongly, leading to excitation and radiationless transitions

```
examples: CH<sub>4</sub>, C<sub>4</sub>H<sub>10</sub>, CO<sub>2</sub>
```

3.4 Ionization chamber

no gas gain, charges move in electric field and induce signal in electrodes.

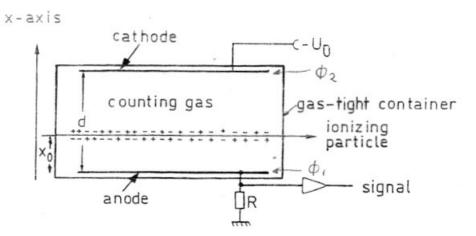

2 electrodes form parallel plate capacitor.

consider motion of a free charge q: electric field does work, capacitor is charged (lowering in energy of capacitor).

$$q\vec{\nabla}\Phi\cdot d\vec{x} = dq_i\cdot U_0$$

leads to induced current

$$\begin{split} \textit{I}_{\text{ind}} &= \quad \frac{q}{U_0} \vec{\nabla} \Phi \cdot \vec{v_D} \\ \text{with } \vec{E} &= \quad -\vec{\nabla} \Phi \text{ and } U_0 = \Phi_1 - \Phi_2 \end{split}$$

Principle of operation of a planar ionization chamber

- current is constant while charge is drifting
- total induced signal (charge) independent of x_0
- signal induced by electrons

$$q_- = \frac{N_e}{U_0} (\Phi(x_0) - \Phi_1)$$

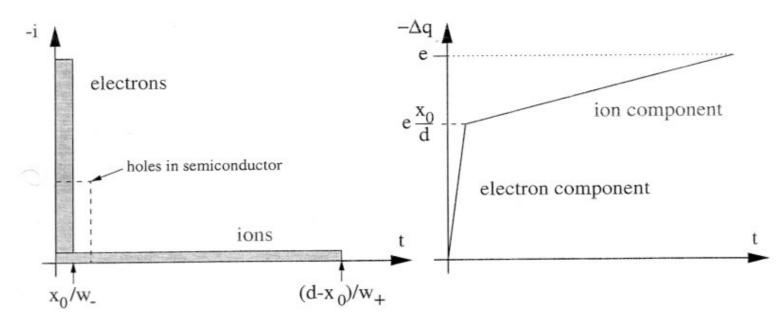

signal induced by ions

$$\Delta q_+ = -rac{N_e}{U_0}(\Phi(x_0)-\Phi_2)$$

• $|N_{ion}| = |N_e|$, but opposite charge \rightarrow total $\Delta q = \Delta q_- + \Delta q_+ = N_e$

practical problem: ion comparatively slow $w_+ = 10^{-3} \dots 10^{-2} w_-$ (see mobilities above) (except for semiconductors: typ. $w_+ \approx 0.5 w_-$)

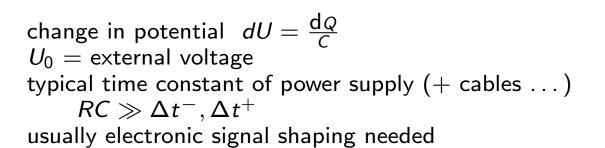

Δ

Induced current and charge for parallel plate case, ratio w_{-}/w_{+} decreased for purpose of illustration.

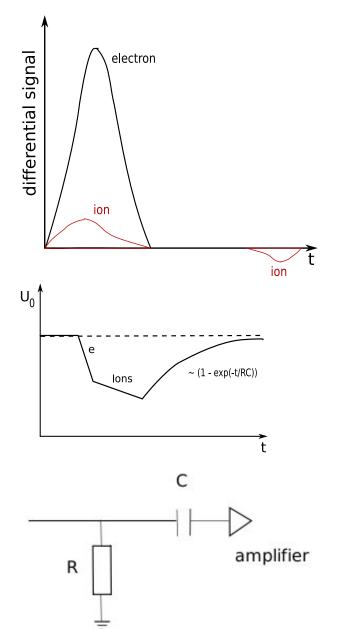

signal generated during drift of charges

- induced current ends when charges reach electrodes
- induced charge becomes constant (total number) N_e)
- signal shaping by differentiation (speed of read-out) \rightarrow suppresses slow ion component

Signal shaping by RC-filter choose e.g. $\Delta t^- \ll RC \ll \Delta t^+$ damps ion component

$$\Delta U = \Delta U^{-} + \Delta U^{+}$$
$$= \frac{\Delta Q^{-}}{C} + \frac{\Delta Q^{+}}{C}$$

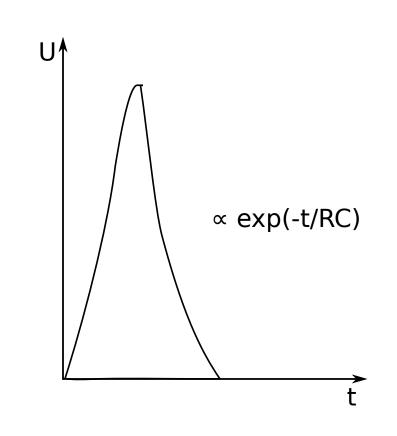

where ΔQ^{+-} is the charge induced in the anode by motion of ions and electrons for total number of ionization events in gas N_e

 $\Delta Q^{-} = N_e \frac{\Phi(x_0) - \Phi_1}{U_0}$ $= N_e \frac{x_0}{d}$ $\Delta Q^+ = -N_e rac{\Phi(x_0) - \Phi_2}{U_0}$ $= N_e \frac{d - x_0}{d}$ without filter $\Delta Q = N_e$, $\Delta U = \frac{N_e}{C}$ with filter $d - x_0 = v^+ \Delta t^+$ $\rightarrow v^+ RC \left(1 - \exp(-\frac{\Delta t^+}{RC})\right)$

damping of ion component

fast rise and decrease of signal but now pulse height depends on x_0

trick: introduce additional grid: "Frisch grid" while electrons drift towards Frisch grid, no induced signal on anode, only on Frisch Grid as soon as electrons pass Frisch grid, signal induced on anode

choose U_g such that the *E*-field is unchanged

$$\Delta Q = \Delta Q^- = N_e$$

 $\Delta t^- = rac{d_g}{v^-}$

general difficulty for ionization chambers: small signals example: 1 MeV particle stops in gas

$$egin{array}{rcl} N_e &\simeq& rac{10^6 \ {
m eV}}{35 \ {
m eV}} \simeq 3 \cdot 10^4 \ C &\simeq& 100 \ {
m pF} \ \Rightarrow \Delta U_{max} &=& rac{3 \cdot 10^4 \cdot 1.6 \cdot 10^{-19} \ {
m C}}{10^{-10} \ {
m F}} \ =& 4.6 \cdot 10^{-5} \ {
m V} \end{array}$$

need sensitive, low-noise preamplifier

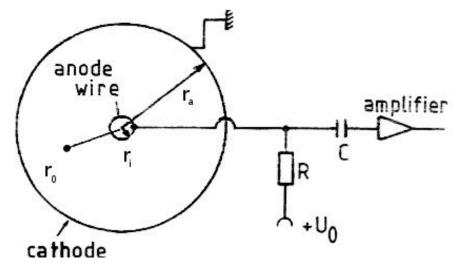

Ionization chamber

application: e.g. cylindrical ionization chamber for radiation dosimetry

$$\vec{E}(r) = -\frac{U_0}{r \ln r_a/r_i} \hat{e}_r$$

ionization at radius r_0 :

$$\Delta t^{-} = \int_{r_0}^{r_i} \frac{\mathrm{d}r}{v^{-}(r)} = -\int \frac{\mathrm{d}r}{\mu^{-}E}$$
$$= -\int_{r_0}^{r_i} \frac{\mathrm{d}r}{\mu^{-}U_0} r \ln \frac{r_a}{r_i}$$
$$= \frac{\ln(r_a/r_i)}{2\mu^{-}U_0} (r_0^2 - r_i^2)$$

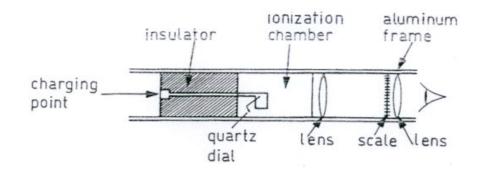

Principle of operation of a cylindrical ionization chamber

 I_0 : typical ionization length, the centroid of the avalanche is this amount away from the wire

$$\Delta Q^{-} = \frac{N_e}{U_0} \int E(r) \, \mathrm{d}r = \frac{N_e}{\ln(r_a/r_i)} \ln \frac{r_i}{l_0} \qquad \Delta U^{-} = \Delta Q^{-}/C$$
$$\frac{\Delta U^{+}}{\Delta U^{-}} = \frac{\ln(r_a/l_0)}{\ln(r_i/l_0)} \qquad r_a \gg r_i \quad \rightarrow \quad \Delta U^{+} \gg \Delta U^{-}$$

in cylindrical geometry, ion signal dominates by typically factor 100.

Dosimeter for Ionization

Construction of an ionization pocket dosimeter

- cylindrical capacitor filled with air
- initially charged to potential U_0
- ionization continuously discharges capacitor
- reduction of potential ΔU is measure for integrated absorbed dose (view e.g. via electrometer)

other applications: measure energy deposit of charged particle, should be highly ionizing (low energy) or even stop (then measure total kinetic energy) nuclear physics experiments with energies of 10 to 100 MeV combination of ΔE and E measurements \rightarrow particle identification (nuclei)

3.5 Proportional Counter

gas amplification as described above

$$N = A \cdot N_e$$

with a gas gain in vicinity of wire

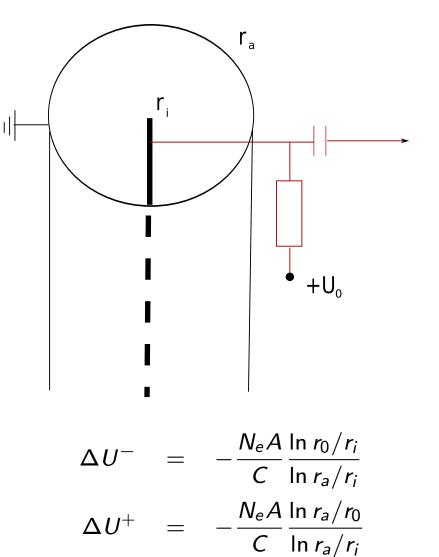

$$A = \exp \int_{r_k}^{r_i} \alpha(x) \mathrm{d}x$$

charge avalanche typically builds up within 20 μm effectively it starts at $r_0 = r_i + k\lambda$

k: number of mean free paths needed for avalanche formation

 λ : mean free paths of electrons (order μ m)

 $(2^{10} \cong 1000 \quad 2^{17} \cong 10^5)$

$$\frac{\Delta U^+}{\Delta U^-} = \frac{\ln r_a/r_0}{\ln r_0/r_i} = R$$

 $r_a=1$ cm, $r_i=30~\mu$ m, $k\lambda=20~\mu$ m for Ar at $P_{
m atm}$ $ightarrow R\simeq 10$

In a proportional counter the signal at the anode wire is mostly due to ion drift!

rise time for electron signal as discussed above $\Delta t^{-} = \frac{\ln(r_a/r_i)}{2\mu^{-}U_0} (r_0^2 - r_i^2) \quad \text{order of ns for } \mu^{-} = 100 - 1000 \text{ cm}^2/\text{Vs}$ and $U_0 \cong \text{several } 100 \text{ V}$ ion signal Δt^+ slow, order of 10 ms \rightarrow differentiate with $R_{\text{diff}} \cdot C$

in case $R_{\text{diff}} \cdot C = 1$ ns \rightarrow time structure of individual ionization clusters can be resolved

Typical set-up

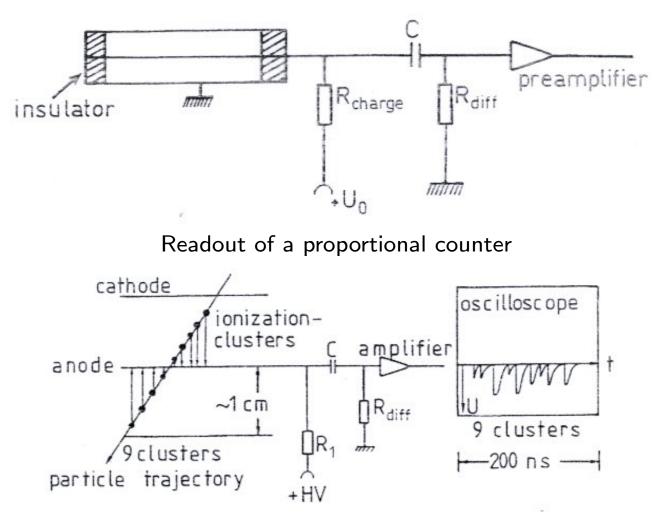

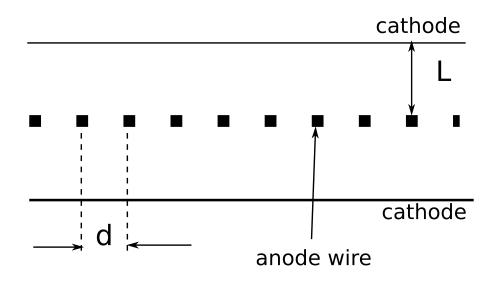

Illustration of the time structure of a signal in the proportional counter

Application outside particle physics: particularly suited to measure X-rays, e.g. 'X-ray imaging' with special electrode geometries for experiments involving synchrotron radiation (high rates!)

Multi-wire proportional chamber

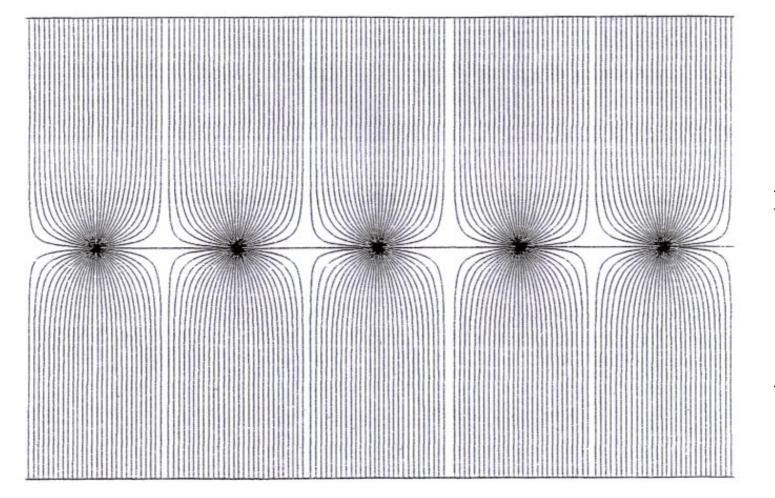

most important application: Multi-wire proportional chamber MWPC

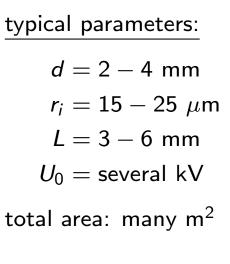

planar arrangement of proportional counters without separating walls G. Charpak et al. NIM 62 (1968) 202 Nobel prize 1992, Rev. Mod. Phys. 65 (1993) 591

allows: tracking of charged particles, some PID capabilities via dE/dxlarge area coverage, high rate capability

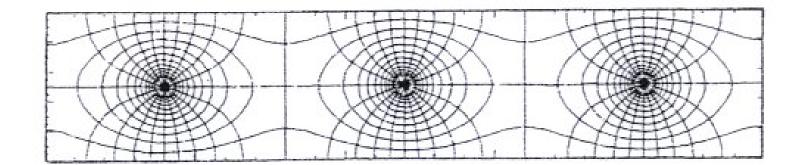

as compared to cylindrical arrangement field geometry somewhat different

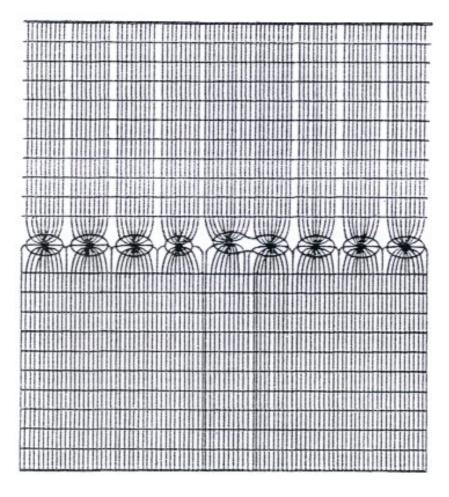

typical geometry of electric field lines in multi-wire proportional chamber

in vicinity of anode wire: radial field far away homogeneous (parallel-plate capacitor)

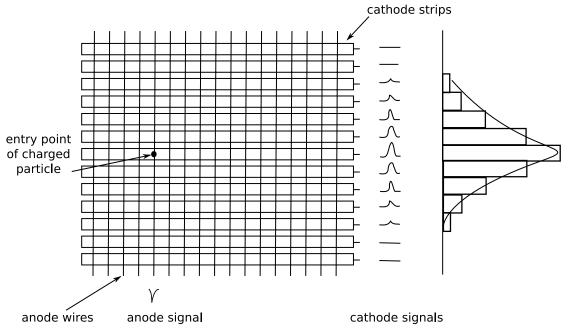

Field lines and equipotential lines

Difficulty:

even small geometric displacement of an individual wire will lead to effect on field quality.

need of high mechanical precision, both for geometry and wire tension (electrostatic effects and gravitational wire sag, see below)

- electrons from primary and secondary ionization drift to closest anode wire
- in vicinity of wire gas amplification → formation of avalanche ends when electrons reach wire or when space charge of positive ions screens electric field below critical value
- signal generation due to electron- and (mostly) slow ion-drift

typical space point resolution:

since only information about closest wire \rightarrow

 $\delta_{\rm x}=d/\sqrt{12}=$ 577 $\,\mu{
m m}$ for d= 2 mm

not very precise and only 1-dimensional

can be improved by segmenting cathode and read-out of induced signal

the center of gravity of signals on cathode strips can be determined with precision of $50 \dots 300 \ \mu m!$ use charge sharing between adjacent strips

Note: The dimension with good resolution is along the wire, perpendicular always $d/\sqrt{12}$.

Resolving ambiguities in case of 2 or more hits in one event: different orientation of segmentation in several cathode planes

two particles traversing MWPC: with only one orientation of segmentation (strips) possibilities •• and oo cannot be distinguished and one obtains 4 possible coordinates for tracks: 2 real and 2 'ghosts', resolved by second induced strip pattern

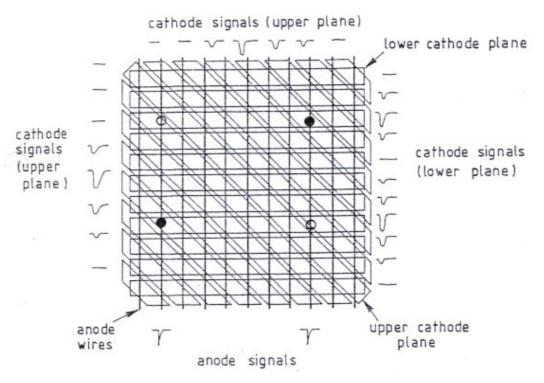

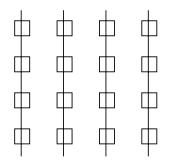

Illustration of the resolution of ambiguities for two particles registered in a multi-wire proportional chamber

for high hit density environment segmentation of cathode into pads truly 2-d measurement.

but: number of read-out channels grows quadratically with area (\$\$)

Stability of wire geometry I

Can we make resolution better and better by putting wires closer and closer? practical difficulty in stringing wires precisely closer than 1 mm fundamental limitations: stability of wire geometry

- electrostatic repulsion between anode wires, in particular for long wires
 - \rightarrow can lead to 'staggering'

to avoid this, the wire tension T has to be larger than a critical value T_0 given by

$$U_0 \leq \frac{d}{lC}\sqrt{4\pi\epsilon_0 T_0}$$
 with wire leng wire distance with capacity

wire length *I*
wire distance *d*
capacity per unit length for cylinder
$$C = \frac{4\pi\epsilon_0}{2\ln(r_a/r_i)}$$

approximation for MWPC with distance anode-cathode $L \gg d \gg r_i$

$$C = \frac{4\pi\epsilon_0}{2\left(\frac{\pi L}{d} - \ln\frac{2\pi r_i}{d}\right)}$$

leading to

$$T_0 \ge \left(\frac{U_0I}{d}\right)^2 4\pi\epsilon_0 \left[\frac{1}{2\left(\frac{\pi L}{d} - \ln\frac{2\pi r_i}{d}\right)}\right]^2$$

with l = 1 m, U_0 = 5 kV, L = 10 mm, d = 2 mm, r_i = 15 μ m \rightarrow T_0 = 0.49 N (\simeq 50 g)

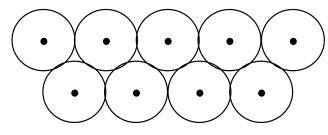

Stability of wire geometry II

 \blacksquare for horizontal wires also gravity \rightarrow sag

$$f = \frac{\pi r_i^2}{8} \rho g \frac{l^2}{T} = \frac{m l g}{8T}$$

gold-plated W-wire $r_i = 15 \ \mu m$, T as above $\rightarrow f = 34 \ \mu m$ \rightarrow visible difference in gain

some of these problems avoided by 'straw tube chambers' (assembly of single-wire proportional counters):

cylindrical wall = cathode aluminized mylar foil introduced in 1990ies

further big (!) advantage: a broken wire affects only 1 cell, not entire chamber straw diameter: 5 - 10 mm, can be operated at over-pressure, space point resolution down to 160 μ m (e.g. LHCb Outer Tracker) **short drift lengths**: enable high rates

operation in magnetic field without degradation of resolution concept employed in several LHC detectors

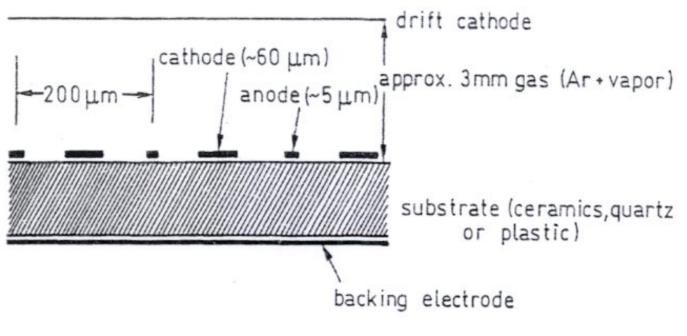

can wires be avoided entirely?

ease of construction stability

. . .

anode can actually be realized by microstructures on dielectrics

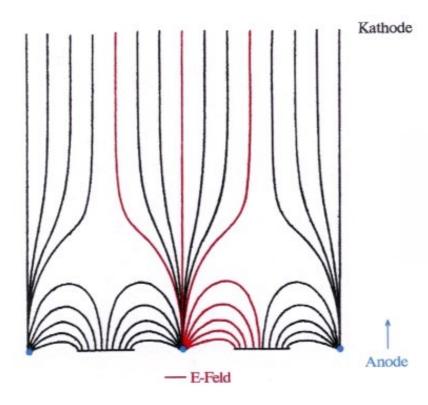

example: microstrip gas detector (developed in 1990ies)

Schematic arrangement of a microstrip gas detector

Proportional counter

schematics of a microstrip gas chamber

directly above anode strip high density of field lines

advantages

- ions drift only 100 μ m
- high rate capability without build-up of _ space charge
- resolution

fine structures can be fabricated by electron lithography on ceramics, glass or plastic foil on which a metal film was previously evaporated.

problems

charging of isolation structure

 \rightarrow time-dependence of gas gain

 \rightarrow sparks, destruction of anode structure, corrosion of insulator

basically not a successful concept - lifetime of detector too limited

Gas electron multiplier

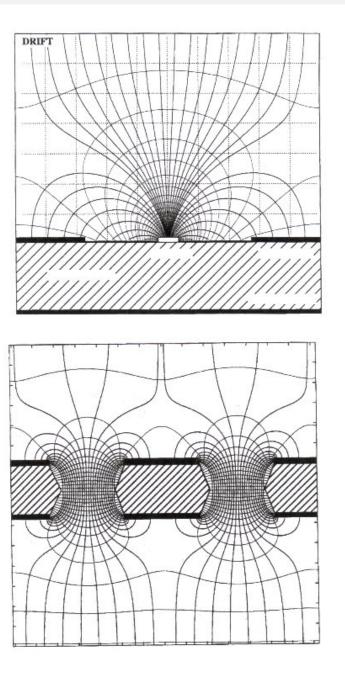

a possible solution: pre-amplification with GEM foil

GEM: gas electron multiplier invented by F. Sauli (CERN) (~1997)

allows reduced electric field in vicinity of anode structures.

but: ease of construction again partly eliminated and danger of discharge on foil (huge capacitance)

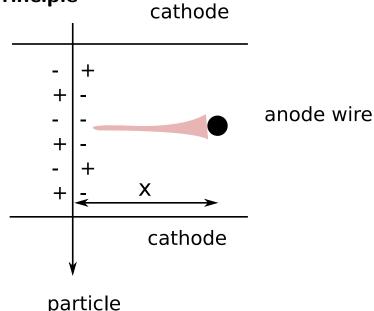

upgrade of Alice TPC for 50 kHz PbPb collisions based on quadruple GEM layers challenge: to keep ion feedback below 1 %

3.6 Drift chambers

invented by A. Walenta, J. Heintze in 1970 at Phys. Inst. U.Heidelberg (NIM 92 (1971) 373)

time measurement:

$$x = v_D^- \cdot \Delta t$$

 v_D^- : drift velocity of electrons

or, in case drift velocity changes along path

$x = \int$	$v_D^-(t) dt$
------------	---------------

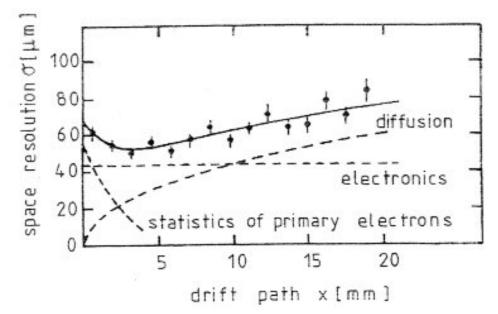

needs well defined drift field \rightarrow introduce additional field wires in between anode wires. but: In that case number of anode wires can be reduced in comparison to MWPC at improved spatial resolution

$$v_D^- \simeq 5 \text{ cm}/\mu \text{s}$$

time resolution of front end electronics $\sigma_t \simeq 1 \text{ ns}$ $\sigma_x \simeq 50 \ \mu \text{m}$ is possible

but the resolution is affected by diffusion of drifting electrons and statistical fluctuations in primary ionization (in particular in vicinity of wire).

factors affecting spatial resolution in a drift chamber:

spatial resolution in a drift chamber as a function of the drift path

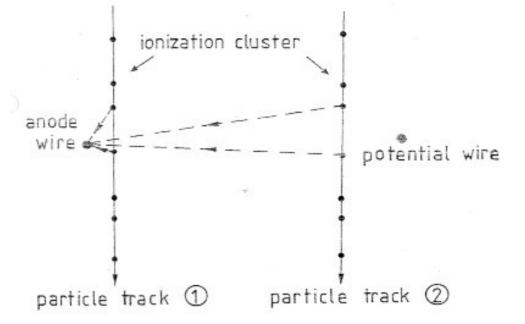

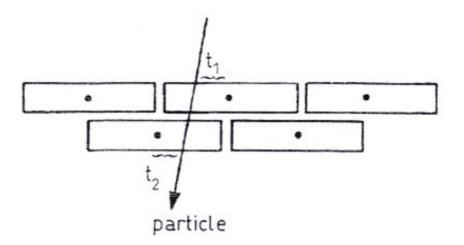

illustration of different drift paths for 'near' and 'distant' particle tracks to explain the dependence of the spatial resolution on the primary ionization statistics **Difficulty**: time measurement cannot distinguish between particle passing to the left or to the right of the anode wire \rightarrow 'left-right ambiguity'

resolution of the left-right ambiguity in a drift chamber

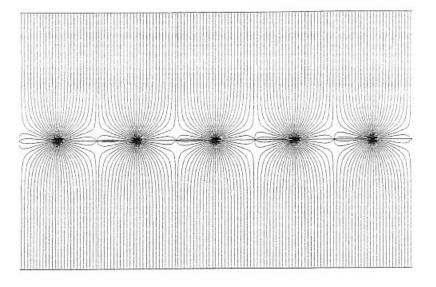

need 2 layers displaced relative to each other by half the wire distance: 'staggered wires'

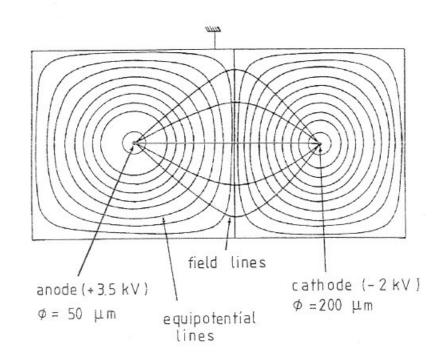

How to achieve field quality good enough for drift chamber?

in a MWPC in between anode wires there are regions of very low electric field (see above)

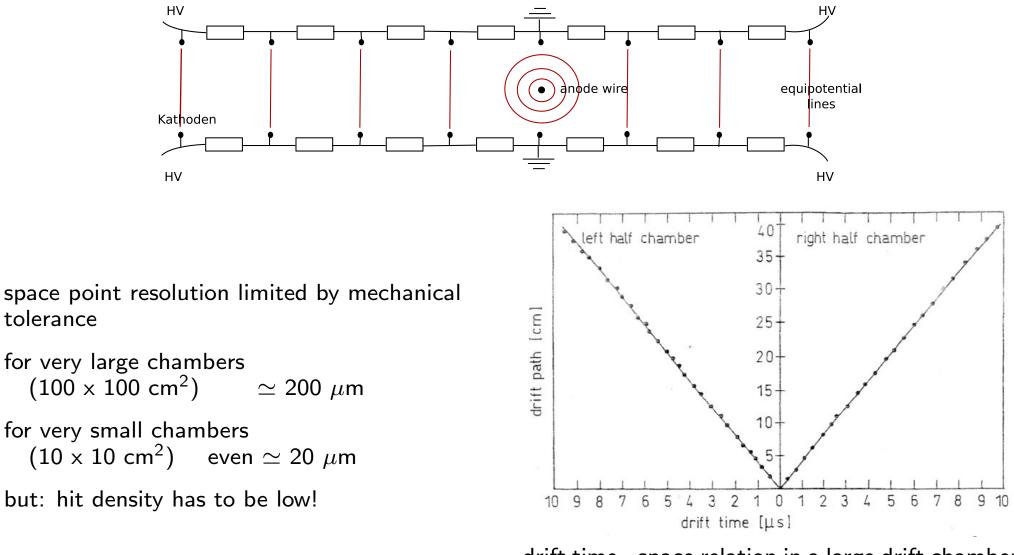

the introduction of additional 'field wires' at negative potential relative to anode wires strongly improves the field quality

essential for drift chamber where spatial resolution is determined by drift time variations and not by segmented electrode structure

one can build very large drift chambers; in this case one introduces a voltage divider by cathode strips connected via resistors, very few or even only one wire.

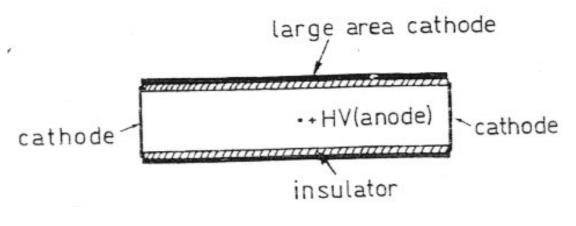

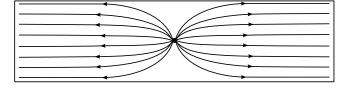

drift time - space relation in a large drift chamber $(80 \times 80 \text{ cm}^2)$ with only one anode wire (Ar + iso-butane 93/7)

tolerance

field can even be formed by charging up of insulating chamber wall with ions after some charging time ions cover insulating layer, no field line end there

Resistive plate counter:

Principle of construction of an electrodeless drift chamber

After charging the insulating layer with ions

3.7 Cylindrical wire chambers

in particular for experiments at storage rings (colliders) to cover maximum solid angle

- initially multi-gap spark chambers, MWPC's
- later cylindrical drift chambers, jet chambers
- today time projection chambers (TPC)

generally these cylindrical chambers are operated in a magnetic field \rightarrow measurement of radius of curvature of a track \rightarrow momentum (internally within one detector)

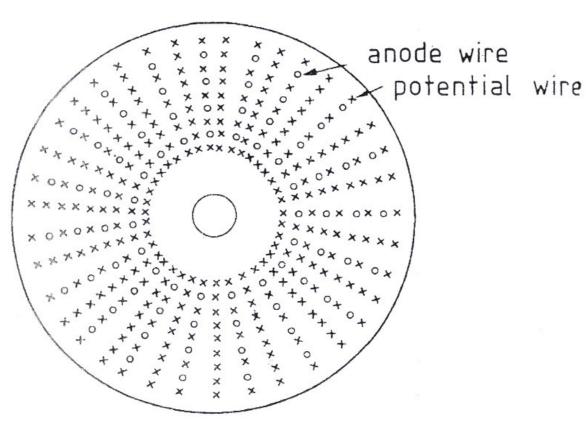

$$p (\text{GeV/c}) = 0.3 \cdot B (\text{T}) \cdot \rho (\text{m})$$

Principle of a cylindrical drift chamber I

principle of a cylindrical drift chamber: wires in axial direction (parallel to colliding beams **and** magnetic field)

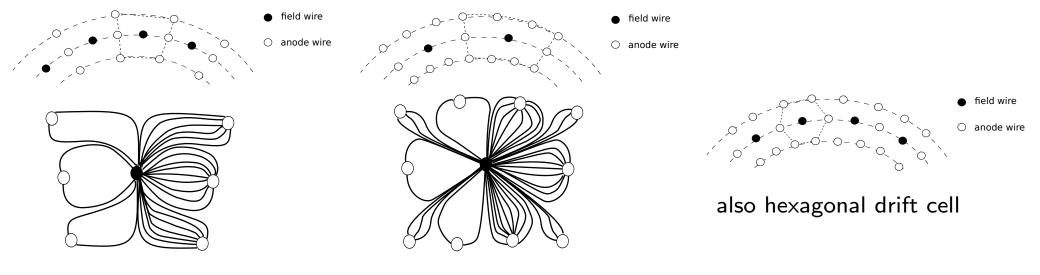

alternating anode and field wires

- one field wire between 2 anode wires
- cylindrical layers of field wires between layers of anode wires \rightarrow nice drift cells

Principle of a cylindrical drift chamber II

different drift cell geometries:

open drift cell

closed drift cell

always thin anode wires ($\emptyset \simeq 30 \ \mu m$) and thicker field wires ($\emptyset \simeq 100 \ \mu m$), generally field quality better for more wires per drift cell, but:

- more labor-intensive construction
- wire tension enormous stress on end plates, e.g. for chamber with 5000 anode and 15000 field wires \rightarrow 2.5 t on each endplate

Determination of coordinate along the wire

 current measurement on both ends of anode wire charge division, precision about 1% of wire length

$$z \propto \frac{I_1 - I_2}{I_1 + I_2}$$

- time measurement on both ends of wire
- 'stereo wires': layer of anode wires inclined by small angle γ ('stereo angle') $\rightarrow \sigma_z = \sigma_x / \sin \gamma$

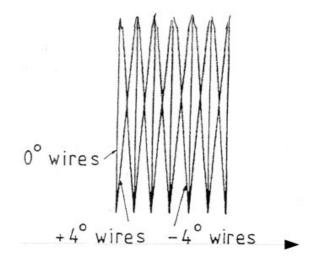

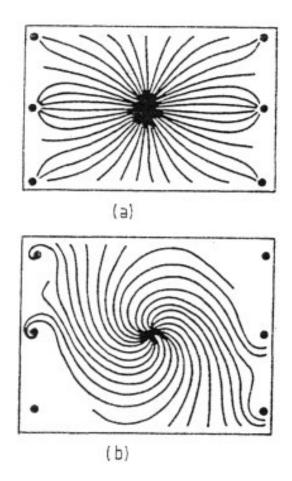

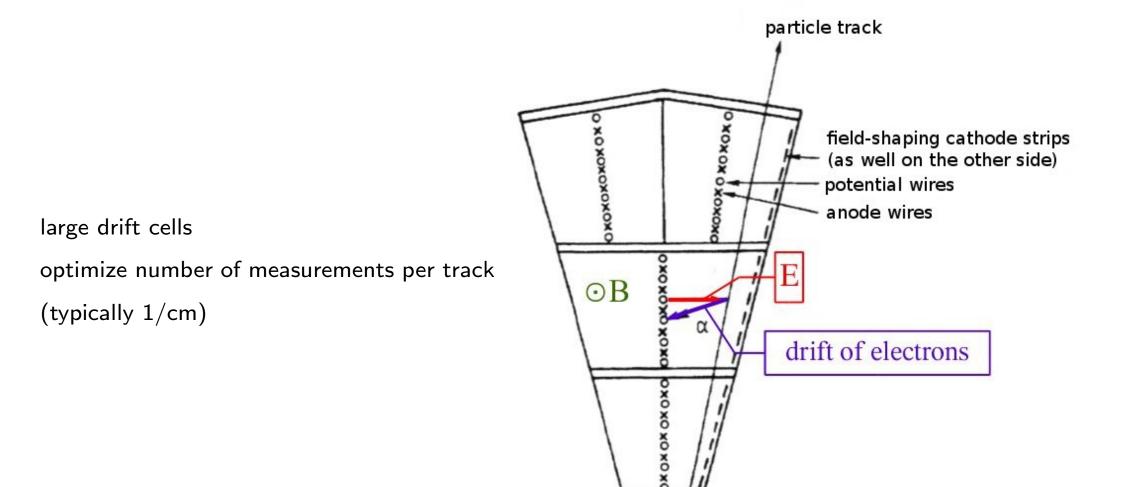

illustration of the determination of the coordinate along the anode stereo wires

in general drift field E perpendicular to magnetic field $B \rightarrow \text{Lorentz angle}$ for drifting charges

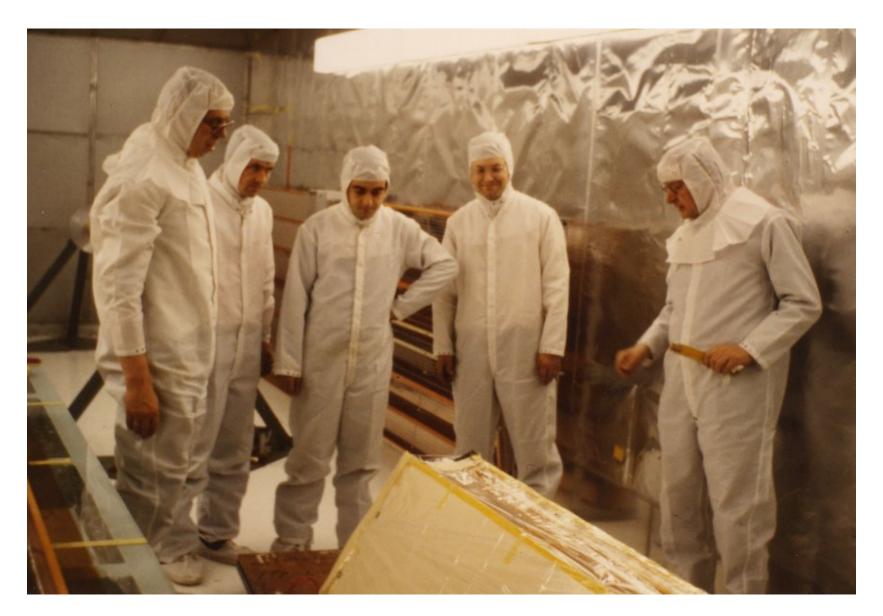

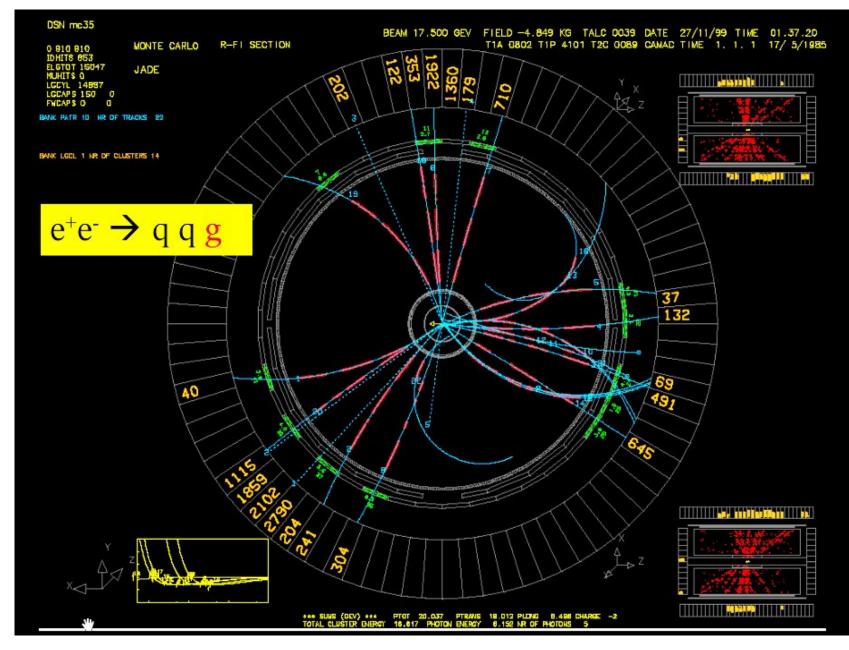

drift trajectories in an open rectangular drift cell a) without and b) with magnetic field

3.8 Jet drift chambers

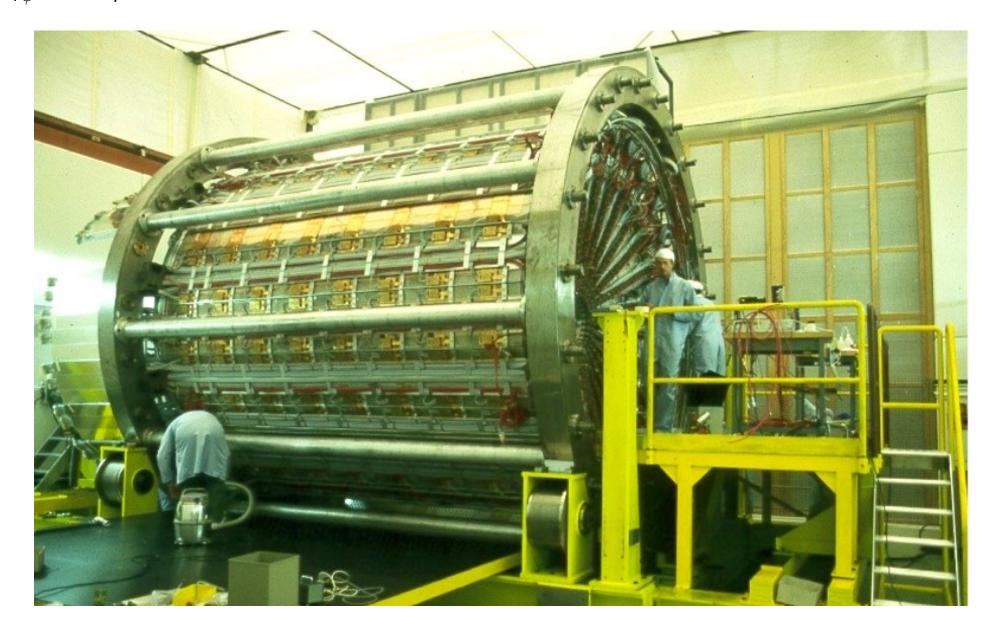

example: JADE jet chamber for PETRA, built by J.Heintze et al. Phys. Inst. U. Heidelberg length: 2.34 m, radial track length: 57 cm, 47 measurements per track $\sigma_{r\phi} = 180 \ \mu m$, $\sigma_z = 16 \ mm$

3-jet event by JADE – measurements taken at PETRA \rightarrow discovery of gluon

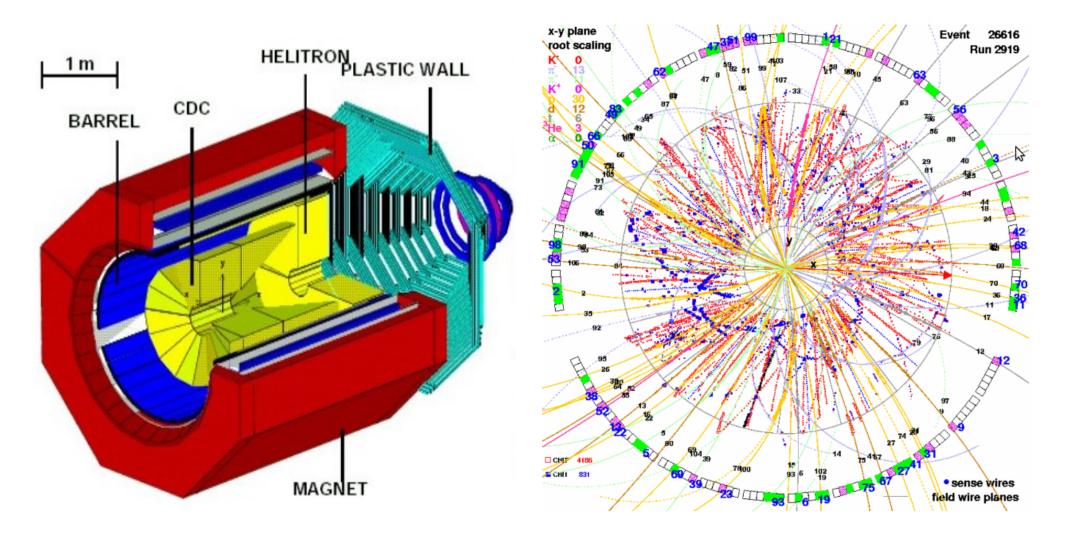

another example: OPAL at CERN LEP: central tracking chamber built by team from Phys. Inst. Heidelberg – Heintze, Wagner, Heuer, ... length: 4 m, radius: 1.85 m, 159 measurements per track, gas: Ar/CH₄/C₄H₁₀ at 4 bar $\sigma_{r\phi} = 135 \ \mu$ m, $\sigma_z = 60 \ mm$

interior of jet chamber of OPAL

application for heavy ion collisions: FOPI (experiment at SIS at GSI): central drift chamber (CDC), D. Pelte and N. Herrmann Phys. Inst. U.Heidelberg

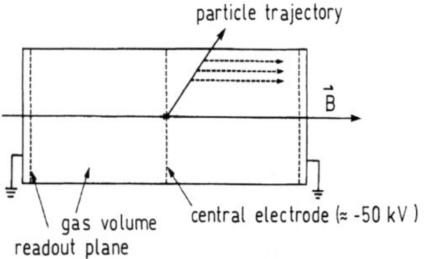

Time Projection Chamber TPC

3.9 Time Projection Chamber TPC

3-dimensional measurement of a track – 'electronic bubble chamber' invented by D. Nygren in 1974 at Berkeley

```
(mostly) cylindrical detector
central HV cathode
MWPCs at the endcaps of the cylinder
electrons drift in homogenous electric fields
towards MWPC, where arrival time and point
and amount of charge are continuously sampled
(flash ADC)
generally with B \parallel E \rightarrow Lorentz angle = 0
```

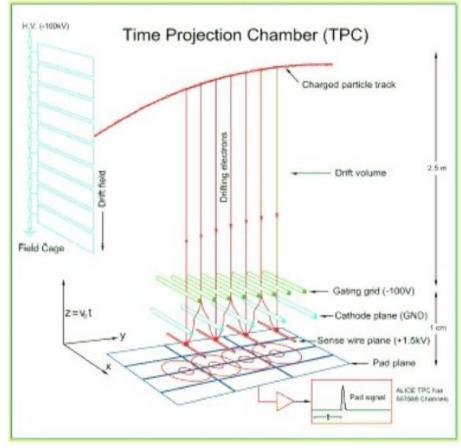

Working principle of a TPC

advantages:

- complete track determination within one detector ightarrow good momentum measurement
- relatively few wires (mechanical advantage)
- since also charge is measured: particle identification via dE/dx
- drift parallel to $B \rightarrow$ transverse diffusion suppressed by factors 10 100 (see above) disadvantages
 - drift time: relatively long tens of microseconds \rightarrow not a high rate detector
 - large data volume

principle of operation of a TPC

continuously sample induced charge or current signals in a MWPC at end of long drift path

z-dim given by drift time

x-dim given by charge sharing of cathode pads

y-dim given by wire/pad number

truly 3-dimensional measurement of ionization points of entire track and in fact of many tracks simultaneously

typical resolution:

z: mm $r\phi$ or x: 150–300 μ m y: mm dE/dx: 5 – 10%, trick: kill Landau tail by evaluating truncated mean

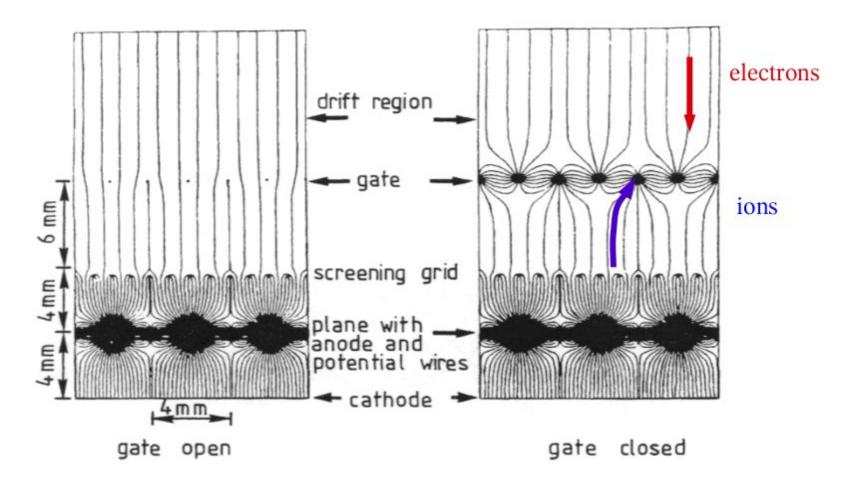

challenges:

- long drift path (attachment, diffusion, baseline)
- large volume (precision)
- large voltages (discharges)
- extreme load in Pb+Pb collisions space charge in drift volume leads to distortion of \vec{E} gating grid opened (fast $\sim 1 \ \mu s$) for triggered events only, otherwise opaque ($\pm \Delta V$)

serious difficulty:

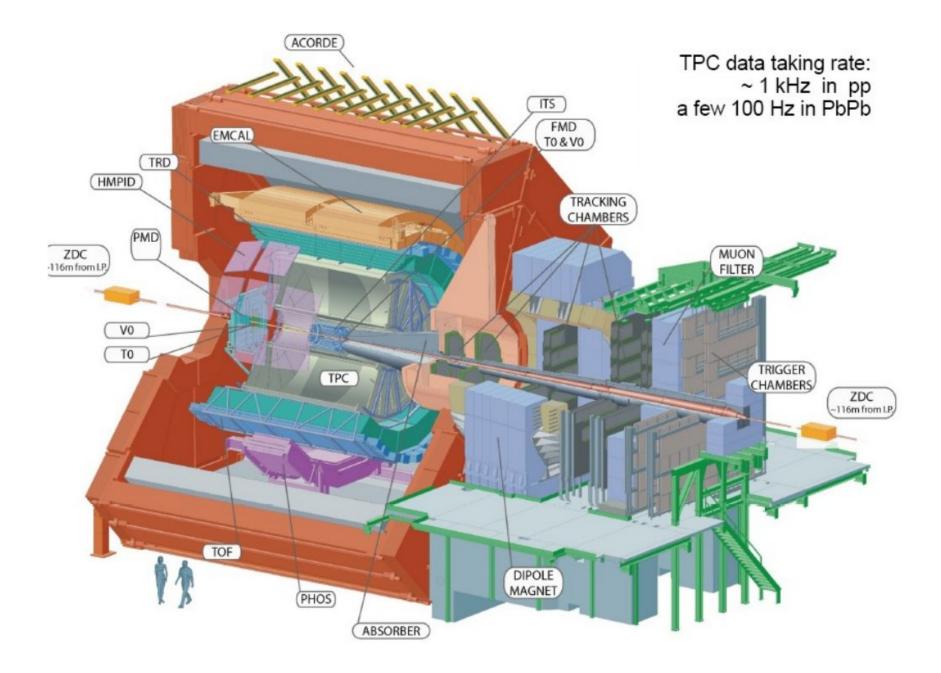

space charge effects since also ions have long drift path and move factor 1000 more slowly, positive ions change effective E-field in drift region, most (5000:1) come from amplification region

trick: invention of gating grid

upon interaction trigger switch gating grid to 'open' for max drift time, then close again \rightarrow all ions from amplification drift toward gating grid and do not enter drift region.

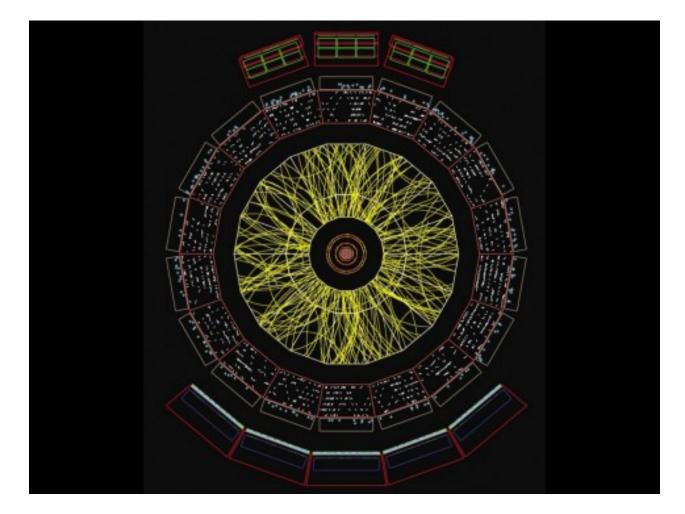

example: the ALICE TPC for LHC Pb + Pb collisions

example: the ALICE TPC for LHC Pb + Pb collisions

the challenge:

identification and reconstruction of 5000 (up to 15000) tracks of charged particle in one event

cut through central barrel of ALICE: tracks of charged particles in a 1 degree segment in θ (1% of all tracks)

J. Stachel (Physics University Heidelberg)

Detectorphysics

example: the ALICE TPC for LHC Pb + Pb collisions

challenges:

- very high multiplicity and desire for very good resolution
 - space charge
 - ightarrow optimize gating grid (even 1% leakage would be deadly)
 - $\rightarrow\,$ rate limitation, good luminosity monitoring
 - occupancy, want to keep it at inner radius below 40%
 - \rightarrow optimize pad sizes and shapes (4 \times 7.5 mm, total 558000)
 - ightarrow 1000 time samples, 159 samples radially
- momentum resolution
 - low multiple scattering, small diffusion
 - $\rightarrow~$ low Z cold gas Ne/CO₂ coupled with small drift cells (occupancy) temperature control to 0.1 K (even resistors need to be cooled) need to know electric field to 10^{-4} precision
 - $\rightarrow~$ small amount of electron-ion pairs
 - $ightarrow\,$ high gas gain of 10000
- event rate
 - limited by drift time (cold gas and not more than 100 kV, 90 μ s)
 - data volume (1 central collision 60 MByte, can't store much more than a few GByte/s)

technical specs:

r = 0.85 – 2.47 m, length 2 × 2.5 m, material budget 3.5% X_0

approximate performance:

 $\sigma(p)/p = 1\% p$, efficiency 97%, $\sigma_{dE/dx}/(dE/dx) \le 6\%$, 100-200 Hz event rate

inside the field cage:

The TPC (Time Projection Chamber) – 3D reconstruction of up to 15 000 charged particle tracks per event

with 95 m^3 largest TPC ever built

central HV electrode 100 kV

field cage: voltage divider with E-field homogeneity of 10^{-4}

in the end caps: 72 multi-wire proportional chambers with cathode pad read-outs

560 million pixels! precision better than 500 μ m in all 3 dimensions, 159 points per track

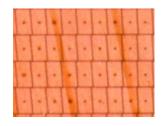

Construction of multi-wire proportional chambers, 3 wire planes plus cathode pad read-out

at GSI, Phys. Inst. U. Heidelberg. U. Bratislava

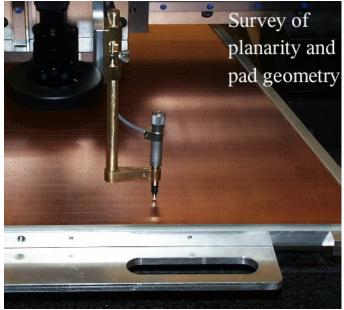

challenge: small spacings, high gas gain, high geometrical precision

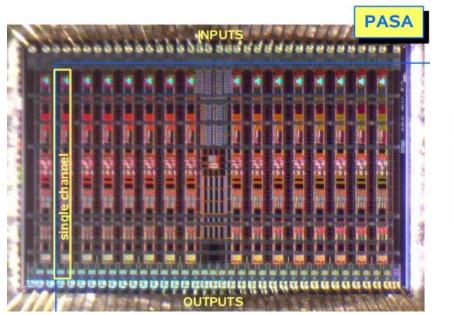

Pad Plane: 5504 pads $(4 \times 7.5 \text{ mm})$

Close-up on the pads

TPC Front End Electronics – 2 ASICS developed at Phys. Inst. U.Heidelberg and CERN, cooperation with ST Microelectronics

excellent performance (now also used by STAR at RHIC)

PASA: low noise preamplifier/shaper

ALTRO: commercial ADC (ST) **in same custom chip** with digital signal processing

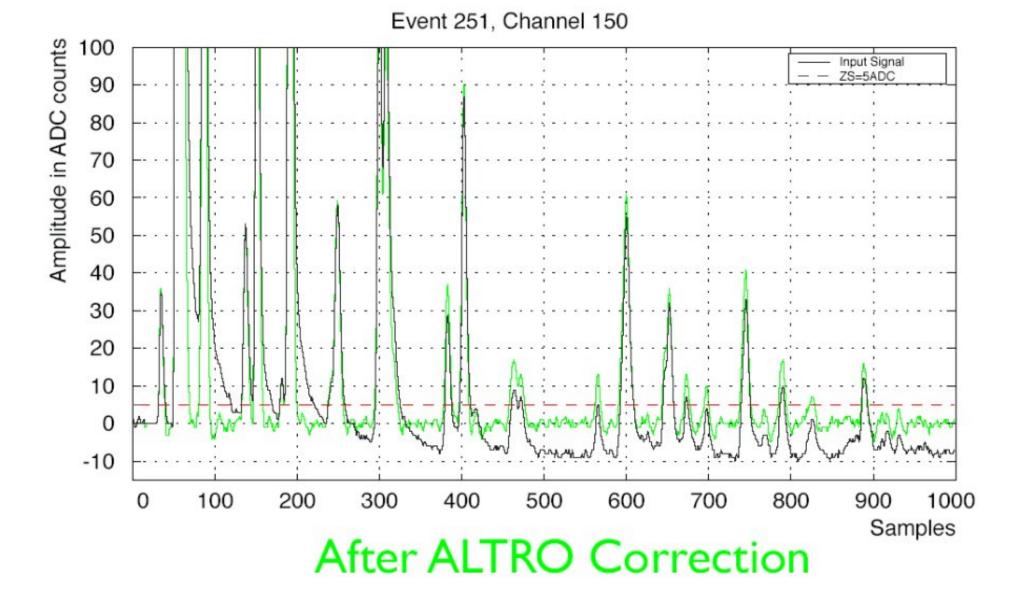

Gas Detectors

electronics needs to be clever:

zero suppression

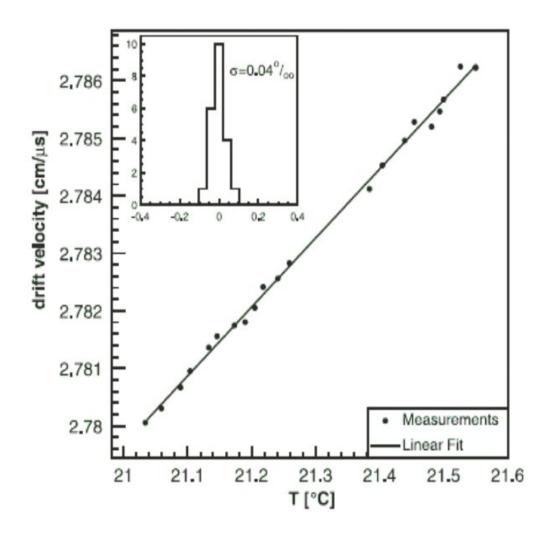

base line restoration

etc. \rightarrow put a lot of intelligence into digital chip after ADC, the ALTRO

J. Stachel (Physics University Heidelberg)

ALICE TPC: drift velocity

converts time into z coordinate extreme precision needed . . . measured with a small TPC (using laser for gas ionization)

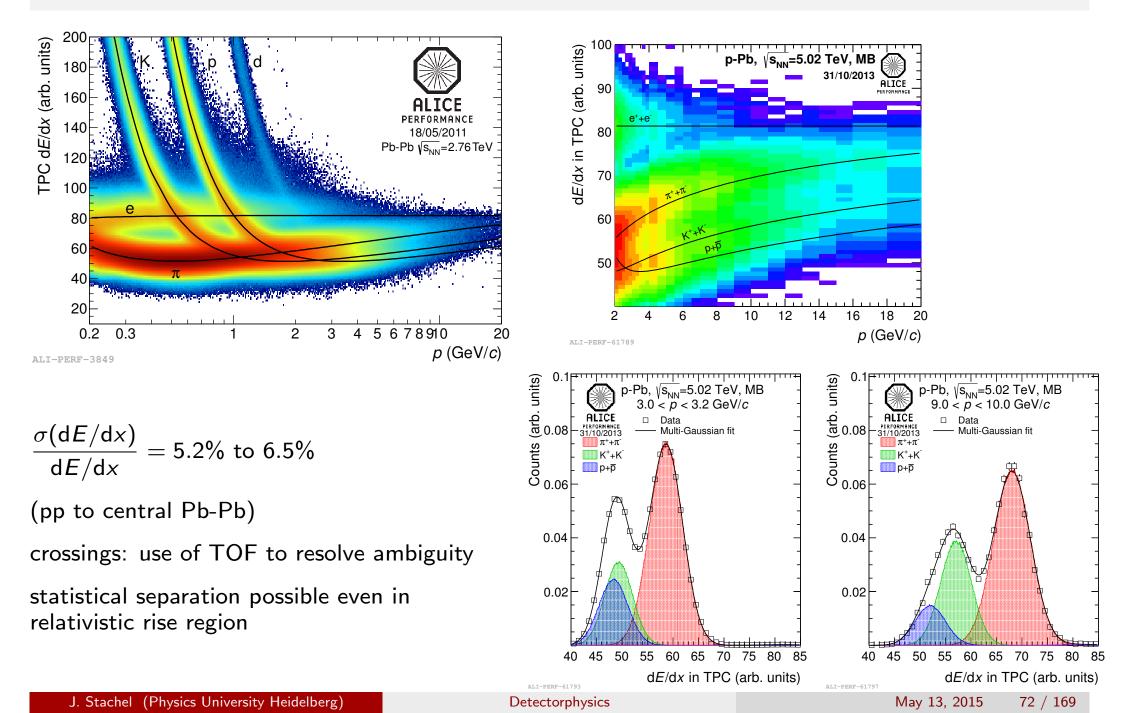

J. Wiechula et al., NIM A 548 (2005) 582

σ_T ≈ 0.1 K ΔT_{max} ≈ 0.3 K 16 14 12 10 8 2 18 18.5 19 19.5 20 20.5 17.5 21 Temperature [°C]

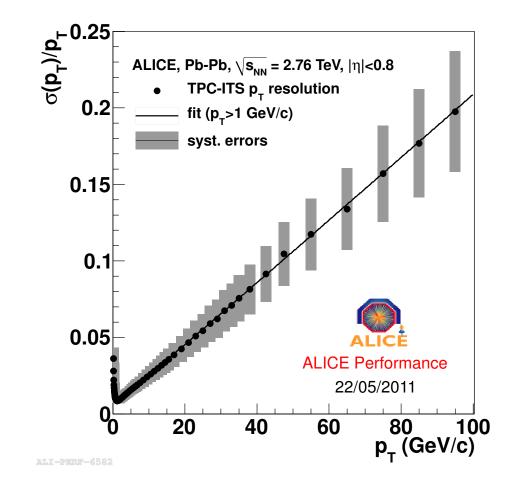

requires temperature stability of 0.1 K TPC FEE dissipates 27 kW TRD as direct neighbor 60 kW 60 independent cooling circuits 500 temperature sensors

Gas Detectors

Performance of the ALICE TPC: particle identification

Performance of the ALICE TPC: momentum resolution

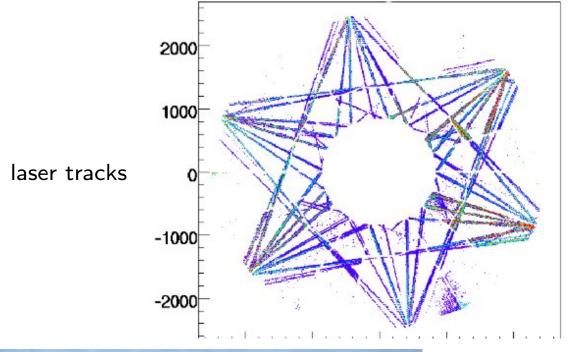

TPC standalone p_{\perp} -resolution

resolution at large p_{\perp} is improved by a factor of about 3 if vertex is included in fit

further improvement by inclusion of track segments of Inner Tracker System and Transition Radiation Detector

TPC fully instrumented and installed in ALICE on Jan. 6, 2007

Gas Detectors

ALICE TPC up and running
